

Question: How can we prove that for the previous problems regarding CFLs (e.g. equality, universality) there is no algorithm that solves them?

Solution: we need a formal definition of algorithm

Let us start with something we know: Java

Can we show that there is no Java program that solves these problems?

Hello - World problem:

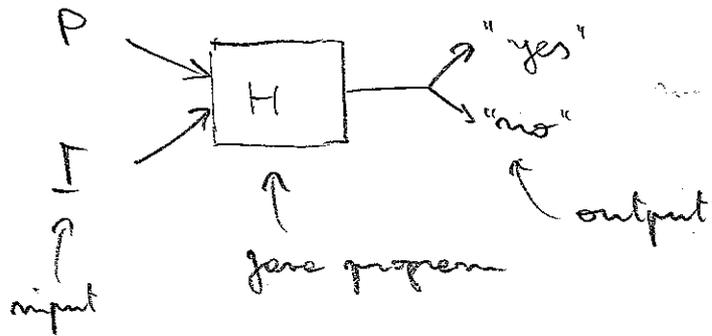

Your first Java program: HW:

```
public class HW {  
    public static void main (String [] args) {  
        System.out.println ("Hello, world");  
    }  
}
```

The first 12 characters output by HW are "Hello, world".

Hello-world problem (HWP): given an arbitrary Java program P and an input I for P , does $P(I)$ print "Hello, world" as its first 12 characters?

Consider a solution to HWP:

Does such a program H exist?

- we could see P for printable statements
- but, how do we know whether they are executed?

To give you an idea how difficult this can become, consider

Fermat's last theorem:

The equation $x^n + y^n = z^n$ has no integer solution for $n \geq 3$.

For $n=2$: a solution is $x=3, y=4, z=5$

For $n \geq 3$; mathematicians have believed that the theorem is true, but no proof was found until recently (proof given by Wiles is very complex, and still under verification)

Consider a simple java program P_1 that:

- 1) needs input n
- 2) for all possible x, y, z do
if $(x^n + y^n = z^n)$
println ("hello, world");

Consider input $n=3$: P_1 prints "hello, world" only if F.L.T is false, otherwise P_1 loops forever.

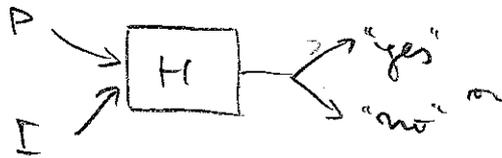

⇒ If we could solve HWP, we would also have proved or disproved F.L.T.

This would be too nice !! Where is the problem?

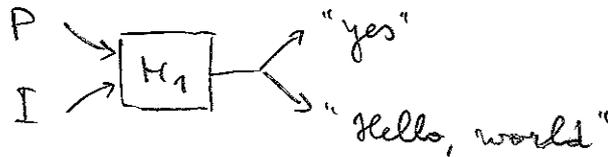

Theorem: There is no Java program H that decides HWP.

Proof: assume H exists and derive a contradiction.

Consider H .

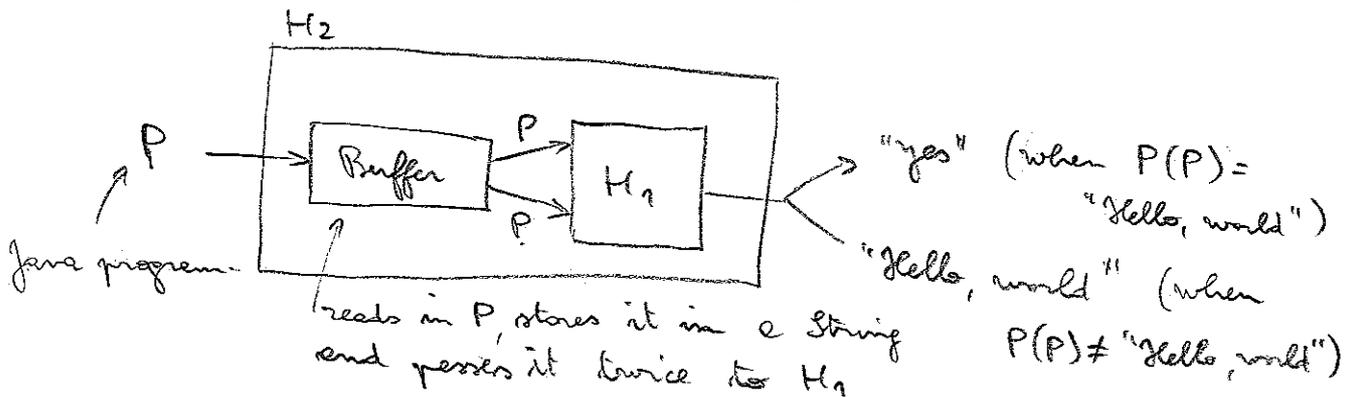

We modify H to H_1 s.t. H_1 prints "Hello, world" instead of "no"

(Note: we have to modify the printed statements in H)

We modify H_1 to H_2 , which takes only input P and feeds it to H_1 as both P and I :

Let us consider $H_2(P)$ when $P = H_2$.

suppose $H_2(H_2) = \text{"yes"}$ ⇒ $P(P) = \text{"Hello, world"}$

suppose $H_2(H_2) = \text{"Hello, world"}$ ⇒ $P(P) \neq \text{"Hello, world"}$

But $P = H_2$ ⇒ contradiction ⇒ H, H_1, H_2 can't exist! Q.E.D

We have shown HWP to be undecidable,
i.e., there cannot be an algorithm (or a program)
that solves it.

(8.4)

We can show that other problems are undecidable by
"reducing" HWP to them

Reductions

Foo-problem: given a program R and its input z , does
 R ever call a function named foo while executing
on input z .

Idea: we reduce the HWP to the foo -problem, i.e.
we show that if it's possible to solve the foo -problem
on (R, z) , then we can solve HWP on (Q, y) , for
any program Q with input y .

Since HWP is undecidable, so is the foo -problem.

Suppose there is a program F that takes as input (R, z)
and decides the foo -problem for (R, z) .

We show how F can be used to construct H that decides
HWP on input (Q, y)

Idea: apply modifications to Q

- 1) rename function foo in Q (if present) to $pippe$.
 $\Rightarrow Q_1$
- 2) add a dummy function foo to $Q_1 \Rightarrow Q_2$
- 3) modify Q_2 to store all its output in some array A .
 $\Rightarrow Q_3$
- 4) modify Q_3 so that after every printable statement it checks array A to see if "Hello, world" has been printed. If yes, then call function $foo \Rightarrow Q_4$

Note: these modifications can be done by a Java program

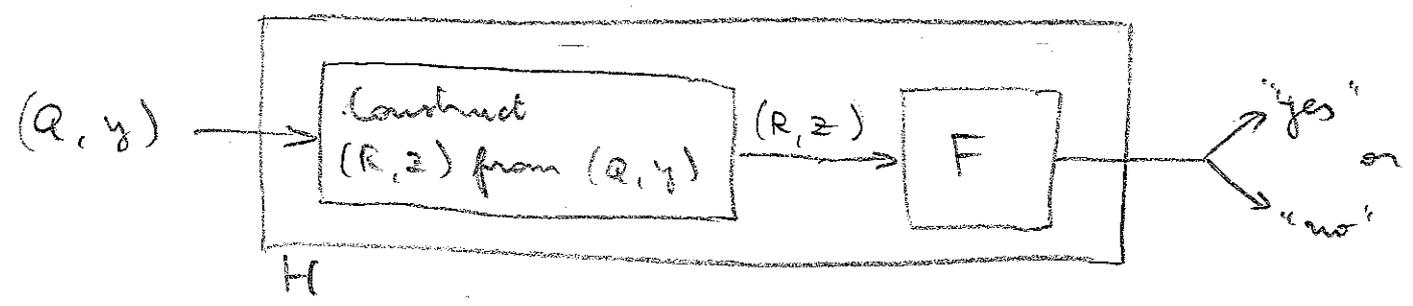

Let $R = Q_4$ and $z = y$

We have by construction:

$Q(y)$ prints "Hello, world" \Leftrightarrow
 $R(z)$ calls function foo .

Hence, we can use F that solves foo -problem on $R(z)$ to construct H that solves HWP on $Q(y)$.

Schematically:

But: since H does not exist, also F cannot exist.

Q.e.d

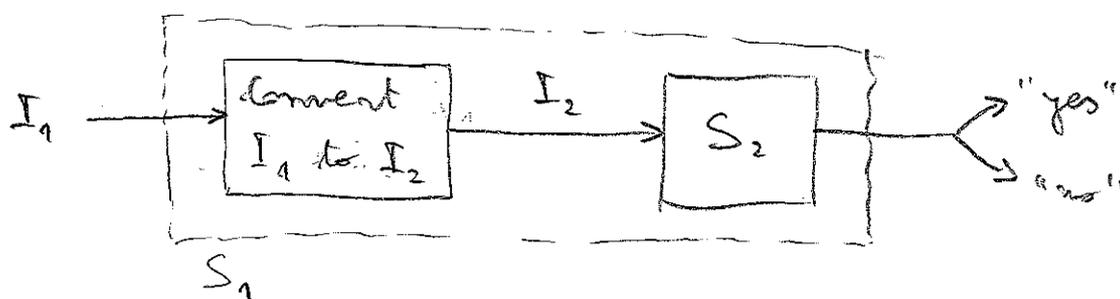

Showing undecidability by reduction from undecidable problem

Problem P_1 taking input I_1 known to be undecidable
 --- P_2 --- I_2 to show undecidable.

Reduction: convert I_1 to I_2 such that

$$P_1(I_1) = \text{"yes"} \quad \text{iff} \quad P_2(I_2) = \text{"yes"}$$

given solution program S_2 for P_2 , we could obtain
 --- S_1 for P_1

Since S_1 does exist, we obtain that S_2 cannot exist
 $\Rightarrow P_2$ is undecidable.

Existence of undecidable problems:

While it was tricky to show that a specific problem is undecidable, it is rather easy to show that there are infinitely many undecidable problems.

We use a counting argument:

- a problem P is a language over Σ (for some finite Σ)
 (the strings in the language represent those instances of P for which the answer is "yes")

\Rightarrow there are uncountably many problems

- an algorithm is a string over Σ' (for some finite Σ')
 \Rightarrow there are countably many algorithms

\Rightarrow There must be (uncountably many) problems for which there is no algorithm.

Turing Machines

15/12/2004 (8.7)

Java (or C, Pascal, ...) programs are not well-suited to develop a theory of computation:

- run-time environment and run-time errors
- complex language constructs
- finite memory
- "state" of the computation is complicated to represent
- would need to show that the results for a specific programming language are in fact general

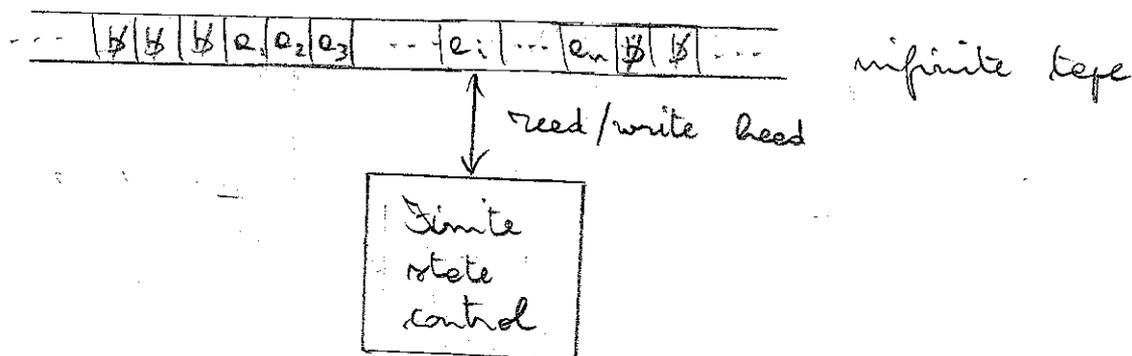

⇒ We resort to an abstract computing device, the Turing Machine (TM)

- simple and universal programming language
- state of computation is easy to describe
- unbounded memory
- can simulate any known computing device

Church-Turing hypothesis:

All reasonably powerful computation models are equivalent to TMs (but not more powerful).

⇒ TMs model everything we can compute.

Programmed by specifying transitions

- move depends on
- current state (finite by many)
 - symbol under the tape head

- effects of a move:
- new state
 - write new symbol on tape cell under the head
 - move head left/right

Observations:

relationship to real computers = CPU \leftrightarrow finite state control
 memory \leftrightarrow tape

"differences" (features lost in the abstraction)

- no random access memory
- limited instruction set

However: a TM can simulate a computer (with a cubic increase in running time - see book 8.6)

Definition A TM $M = (Q, \Sigma, \Gamma, \delta, q_0, \$, F)$

Q ... set of states (finite)

$q_0 \in Q$... initial state

Σ ... input alphabet (finite)

Γ ... tape alphabet (finite)

$F \subseteq Q$... final states

$\$ \in \Gamma$... blank symbol

Conditions: $\Sigma \subseteq \Gamma$, since input is written initially on tape
 $\$ \in \Gamma - \Sigma$, since the rest of the tape is blank

Initially:

- state q_0
- tape contains w surrounded by $\$$
- tape head is at the leftmost cell of the input

Transitions: $\delta: Q \times \Gamma \rightarrow Q \times \Gamma \times \{L, R\}$

$\delta(q, x) = (r, y, d)$ means that

if M is in state q and tape head is over symbol x , then M changes state to r .

- replaces x by y on the tape

- moves tape head by one cell in direction d (left for L, right for R)

The TM is deterministic:

for each $\delta(q, x)$ we have at most one move

($\delta(q, x)$ could also be undefined)

Acceptance: w is accepted by TM M if M , when started with w on the tape, eventually enters a final state

We can assume that all final states are halting, i.e. no transition is defined for them

Rejection:

- halts in non final state (i.e., no transition defined)
- never halts (infinite loop)

Difference between FA/PDA and TM:

FA/PDA scans over w and accepts/rejects when it has reached its end

TM can move back and forth over w and accepts/rejects when it halts or rejects if it loops forever

Example: $L = \{ w \#^* w^T \mid w \in \{0, 1\}^+, \# \in \{0, 1, \#\}^* \}$

- TM idea:
- remember leftmost symbol, erase it
 - move to leftmost symbol after #'s
 - if the two don't match, then reject
 - otherwise replace the symbol by #, move left and start again

$$M = (Q, \Sigma, \Gamma, \delta, q_0, \sqcup, F)$$

$$Q = \{q_0, q_1, \dots, q_7\}$$

$$F = \{q_7\}$$

$$\Sigma = \{0, 1, \#\}$$

$$\Gamma = \{0, 1, \#, \sqcup\}$$

$$\begin{aligned} \delta(q_0, 0) &= (q_1, \sqcup, R) \\ \delta(q_0, 1) &= (q_2, \sqcup, R) \end{aligned} \left. \vphantom{\begin{aligned} \delta(q_0, 0) \\ \delta(q_0, 1) \end{aligned}} \right\} \begin{array}{l} \text{Erase 0 and look for matching 0} \\ \text{" - 1 - - - - - 1} \end{array}$$

$$\begin{aligned} \delta(q_1, 0) &= (q_1, 0, R) \\ \delta(q_1, 1) &= (q_1, 1, R) \\ \delta(q_1, \#) &= (q_3, \#, R) \end{aligned} \left. \vphantom{\begin{aligned} \delta(q_1, 0) \\ \delta(q_1, 1) \\ \delta(q_1, \#) \end{aligned}} \right\} \begin{array}{l} \text{Skip over 0's and 1's,} \\ \text{till \# is found (remembering 0)} \end{array}$$

$$\begin{aligned} \delta(q_2, 0) &= (q_2, 0, R) \\ \delta(q_2, 1) &= (q_2, 1, R) \\ \delta(q_2, \#) &= (q_4, \#, R) \end{aligned} \left. \vphantom{\begin{aligned} \delta(q_2, 0) \\ \delta(q_2, 1) \\ \delta(q_2, \#) \end{aligned}} \right\} \begin{array}{l} \text{" - - - - -} \\ \text{(remembering 1)} \end{array}$$

$$\begin{aligned} \delta(q_3, \#) &= (q_3, \#, R) \\ \delta(q_3, 0) &= (q_5, \#, L) \end{aligned}$$

Skip over #'s, look for 0, and replace it by #.
 Note: if after #'s a 1 or a $\$$ is found, M halts and rejects

$$\begin{aligned} \delta(q_4, \#) &= (q_4, \#, R) \\ \delta(q_4, 1) &= (q_5, \#, L) \end{aligned}$$

As previous one, replacing 0/1 with 1/0.

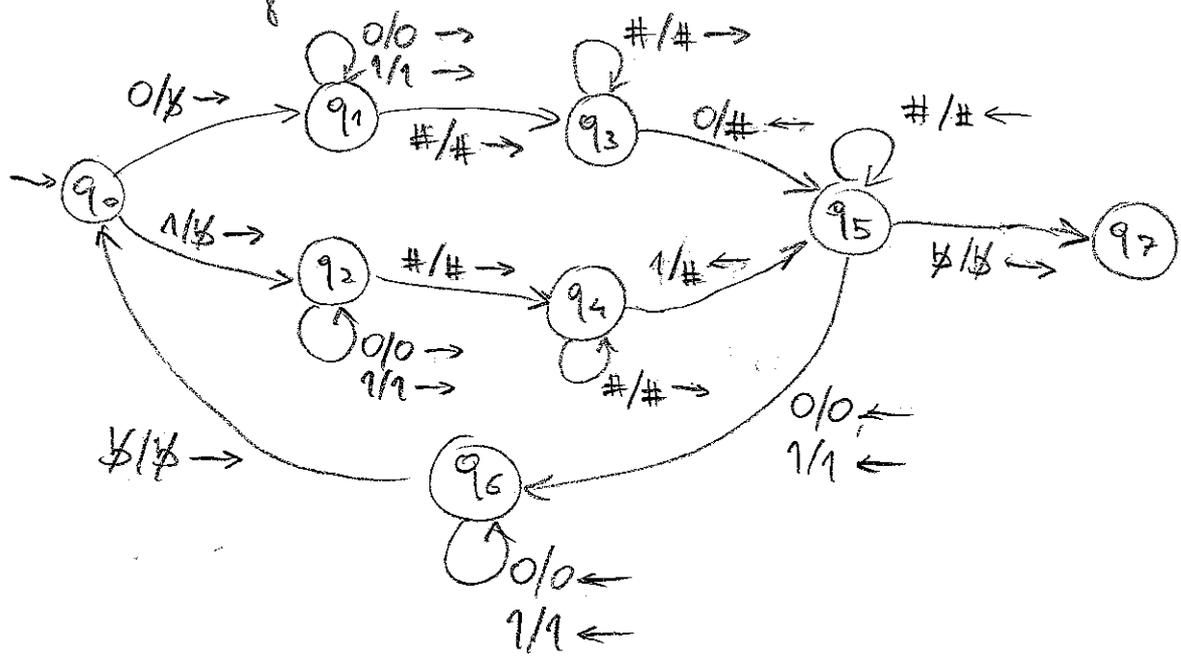

$$\begin{aligned} \delta(q_5, \#) &= (q_5, \#, L) \\ \delta(q_5, 0) &= (q_6, 0, L) \\ \delta(q_5, 1) &= (q_6, 1, L) \\ \delta(q_5, \$) &= (q_7, \$, R) \end{aligned}$$

Move left skipping #'s. If to the left of the #'s a 0 or 1 is found, move to q_6 to skip them also. If $\$$ is found, accept

$$\begin{aligned} \delta(q_6, 0) &= (q_6, 0, L) \\ \delta(q_6, 1) &= (q_6, 1, L) \\ \delta(q_6, \$) &= (q_0, \$, R) \end{aligned}$$

Move left, skipping 0's and 1's, and restart again.

Transition diagram

Instantaneous description (I.D.) or configuration of a TM (8.12)

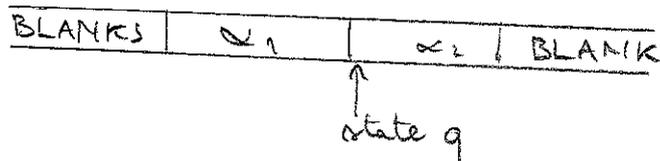

describes the current situation of TM and tape.

$$I.D. = \alpha_1 q \alpha_2 \quad \text{with } q \in Q$$

$$\alpha_1, \alpha_2 \in \Gamma^*$$

- means:
- non-blank portion of tape contains $\alpha_1 \alpha_2$
 - head is on leftmost symbol of α_2
 - machine is in state q

corresponds to

As for PDA's, we use \vdash and \vdash^* to denote the change of I.D. due to transitions.

Example:

$$q_0 01\#01 \vdash q_1 1\#01 \vdash 1q_1\#01 \vdash$$

$$\vdash 1\#q_3 01 \vdash 1q_5\#\#1 \vdash$$

$$\vdash q_5 1\#\#1 \vdash q_6 \cancel{1}\#\#1 \vdash$$

$$\vdash q_0 1\#\#1 \vdash \dots \vdash$$

$$\vdash q_5 \cancel{1}\#\#\# \vdash q_7 \#\#\#$$

↑ accepts

Formal definition of language accepted by a TM M :

$$L(M) = \left\{ w \in \Sigma^* \mid q_0 w \vdash^* \alpha_1 q \alpha_2 \quad \text{with } q \in F \right. \\ \left. \text{and } \alpha_1, \alpha_2 \in \Gamma^* \right\}$$

Notes:

1) We have used TMs for language recognition, which in turn corresponds to solving decision problems

- We can, however, consider also TMs as computing functions:
 - the output (result of the function) is left on the tape

2) The class of languages accepted by TMs are called recursively enumerable

- for a string w in the language
 - the TM halts on input w in a final state
- for a string w not in the language
 - the TM may halt in a non-final state, or
 - it may loop forever

Those languages for which the TM always halts (regardless of whether it accepts or not) are called recursive:

- these languages correspond to recursive functions
- TMs that always halt are a good model of algorithms and they correspond to decidable problems

We present some notational conveniences that make it easier to write TM programs

Idea: use structured states and tape symbols

1) Storage in the state: ("CPU register")

Idea: state names are a tuple of the form

$$[q, D_1, \dots, D_k]$$

D_i : ... acts as stored symbol

q : ... control portion of the state

Example: TM $M = (Q, \Sigma, \Gamma, \delta, q_0, \emptyset, F)$ for $L = 01^* + 10^*$

Idea: M remembers the first symbol and checks that it does not reappear

$$Q = \{ [q_i, a] \mid i \in \{0, 1\}, a \in \{0, 1, -\} \} = \{ [q_0, -], [q_0, 0], [q_0, 1], [q_1, -], [q_1, 0], [q_1, 1] \}$$

$$\Sigma = \{0, 1\}$$

$$\Gamma = \{0, 1, \emptyset\}$$

$$q_0 = [q_0, \emptyset]$$

$$F = \{ [q_1, -] \}$$

Meaning of $[q_i, a]$

- control portion q_i :

q_0 ... M has not yet read its first symbol

q_1 ... M has read its first symbol

- data portion a : a is the first symbol read

transitions:

$$\delta([q_0, _], e) = ([q_1, e], e, R), \text{ for } e \in \{0, 1\}$$

\Rightarrow M remembers in $[q_1, e]$ that it has read e

$$\left. \begin{aligned} \delta([q_1, 0], 1) &= ([q_1, 0], 1, R) \\ \delta([q_1, 1], 0) &= ([q_1, 1], 0, R) \end{aligned} \right\} \begin{array}{l} \text{M moves right as} \\ \text{long as it does not} \\ \text{see the first symbol} \end{array}$$

$$\delta([q_1, e], \$) = ([q_1, -], \$, R), \text{ for } e \in \{0, 1\}$$

\dots M accepts when it reaches the first $\$$

2) Multiple tracks:

Idea: view tape as having multiple tracks, i.e. 1 in each symbol in Γ has multiple components

| | | | | |
|-----|---|---|------------|-----|
| | 0 | * | \$ | |
| ... | 1 | 0 | 0 | ... |
| | a | a | ϵ | |

the symbols on the tape are $\begin{bmatrix} 0 \\ 1 \\ a \end{bmatrix}, \begin{bmatrix} * \\ 0 \\ a \end{bmatrix}, \begin{bmatrix} \$ \\ 0 \\ \epsilon \end{bmatrix}$

Example: $L = \{ww \mid w \in \{0, 1\}^+\}$

We first need to find midpoint, and then we can match corresponding symbols.

To find midpoint: we view tape as 2 tracks

| | | | | | |
|--|---|---|---|---|---|
| | | | * | | |
| | 0 | 1 | 1 | 0 | 1 |

\leftarrow used to put markers on symbols

Hence: $\Gamma = \left\{ \begin{bmatrix} \$ \\ \$ \end{bmatrix}, \begin{bmatrix} \$ \\ 0 \end{bmatrix}, \begin{bmatrix} \$ \\ 1 \end{bmatrix}, \begin{bmatrix} * \\ 0 \end{bmatrix}, \begin{bmatrix} * \\ 1 \end{bmatrix} \right\}$

(note: we need no * over \$)

We put markers on two outermost symbols and move them inwards:

8.16

$$\begin{array}{l}
 \delta(q_0, [i]) = (q_1, [i], R) \\
 \delta(q_1, [i]) = (q_1, [i], R)
 \end{array}
 \left. \vphantom{\begin{array}{l} \delta(q_0, [i]) \\ \delta(q_1, [i]) \end{array}} \right\} \begin{array}{l} \text{move right till end} \\ \text{or first marked symbol} \end{array}$$

$$\begin{array}{l}
 \delta(q_1, [i]) = (q_2, [i], L) \\
 \delta(q_1, [i]) = (q_2, [i], L) \\
 \delta(q_2, [i]) = (q_3, [i], L)
 \end{array}
 \left. \vphantom{\begin{array}{l} \delta(q_1, [i]) \\ \delta(q_1, [i]) \\ \delta(q_2, [i]) \end{array}} \right\} \begin{array}{l} \text{move rightmost mark} \\ \text{one symbol to the left} \end{array}$$

$$\begin{array}{l}
 \delta(q_3, [i]) = (q_3, [i], L) \\
 \delta(q_3, [i]) = (q_0, [i], R)
 \end{array}
 \left. \vphantom{\begin{array}{l} \delta(q_3, [i]) \\ \delta(q_3, [i]) \end{array}} \right\} \begin{array}{l} \text{move left till end} \\ \text{or first marked symbol} \end{array}$$

Note: we have each of the above for $i \in \{0, 1\}$

at the end: head is over first symbol of second w, with a * above it, in state q_0 .

3) Subroutines / procedure calls

Example: shifting over

given: $ID_1 = \alpha q_i x \beta$

want: $ID_2 = \alpha \square q_i x \beta$

for $x \in \Gamma$

$\alpha, \beta \in \Gamma^*$

$\square \in \Gamma$

Subroutine for shifting over can be used repeatedly to create space in the middle of the tape

e.g. to implement a counter

$\$0\$ \rightarrow \$1\$ \rightarrow \$\square1\$ \rightarrow \$01\$ \rightarrow \$10\$ \rightarrow$
 $\rightarrow \$11\$ \rightarrow \$\square11\$ \rightarrow \$011\$ \rightarrow \dots$

Procedure call: $\delta(q_i, x) = ([\uparrow, x], [\uparrow], R)$, $\forall x \in \Gamma$

- remember return state q_i , end erased symbol x
- state q calls procedure

Procedure q for shifting

1) shift 1 cell to the right

$$\delta([\uparrow, x], y) = ([\uparrow, y], x, R) \quad \forall x, y \in \Gamma \text{ with } y \neq \$$$

2) till we have reached end of β

$$\delta([\uparrow, y], \$) = (r, y, L) \quad \forall y \in \Gamma$$

3) return to calling point by moving left

$$\delta(r, y) = (r, y, L) \quad \forall y \neq [\uparrow]$$

4) exit end return to state q_i

$$\delta(r, [\uparrow]) = (q_i, \square, R)$$

In fact, we can implement arbitrary complex procedures, with any kind of parameter passing

Exercise:

redesign the TMs you have seen so far to take advantage of storage in the state, multiple tracks, and subroutines

Extensions to the basic TM

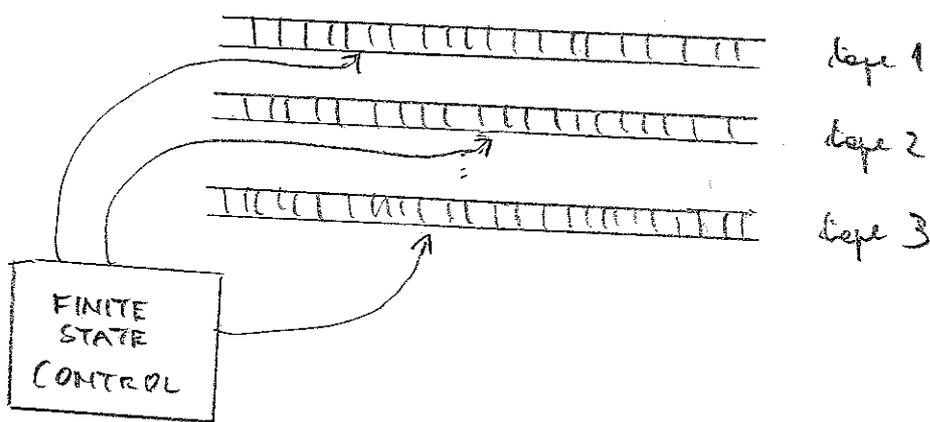

8.48

Note: if the TM seen so far can compute all that can be computed, then it should not become more expressive by extending it

We consider two extensions: - multiple tapes
- nondeterminism

and show that both can be captured by the basic T.M.

1) Multi-tape T.M.

Initially: input w is on tape 1 with tape-head on the leftmost symbol. Other tapes are all blank.

Transitions: specify behaviour of each head independently

$$\delta(q, x_1, \dots, x_k) = (q', (y_1, d_1), \dots, (y_k, d_k))$$

x_i ... symbol under head i

y_i ... new symbol written to head i

d_i ... direction in which head i moves

To simulate k -tape TM M_k with a 1-tape TM M_1 , we use $2k$ tracks in M_1 : for each tape of M_k

- one track of M_1 to store tape content
- one track of M_1 to mark head position with *

| | | | | | | | | |
|--|---|---|---|---|---|---|--|--------|
| | A | B | A | C | B | A | | tape 1 |
| | | | | * | | | | head 1 |
| | 0 | 0 | 1 | 1 | 1 | 0 | | tape 2 |
| | | * | | | | | | head 2 |
| | b | b | a | b | a | b | | tape 3 |
| | | | | | | * | | head 3 |

Each transition of M_k is simulated by a series of transitions of M_1 : $\delta(q, x_1, \dots, x_k) = (r, (y_1, d_1), \dots, (y_k, d_k))$

- start at leftmost head position marker
- sweep right and remember in appropriate "CPU registers" the symbols x_i under each head (note: there are exactly k , and hence finitely many)
- knowing all x_i 's, sweep left, change each x_i to y_i , and move the marker for tape i according to d_i

Note: M_1 needs to remember always how many of the k heads are to its left (uses an additional CPU-register)

The final states of M_1 are those that have in the state-component a final state of M_k .

We can verify that we can construct M_1 so that

$$L(M_1) = L(M_k)$$

(details are straightforward, but cumbersome)

Simulation speed:

22/12/2004

8:20

18/12/2005

Note: - enhancements do not affect the expressive power of a TM
- they do affect its efficiency

Definition: a TM is said to have running time $T(n)$ if it halts within $T(n)$ steps on all inputs of length n .

Note: $T(n)$ could be infinite

Theorem: If M_k has running time $T(n)$, then M_1 will simulate it with running time $O(T(n)^2)$.

Proof: Consider input w of length n .

- M_k runs at most $T(n)$ time on it.
- At each step, leftmost and rightmost heads can drift apart by at most 2 additional cells.
- It follows that after $T(n)$ steps the k heads cannot be more than $2 \cdot T(n)$ apart, and M_k uses $\leq 2 \cdot T(n)$ tape cells

Consider M_1 :

- makes two sweeps for each transition of M_k
- each sweep takes at most $O(T(n))$
- number of transitions of M_k is $\leq T(n)$

It follows that the total running time is $O(T(n)^2)$.

2) Non-deterministic TMs (NTM)

In a (deterministic) TM, $\delta(q, x)$ is unique or undefined

In a NTM, $\delta(q, x)$ is a finite set of triples

$$\delta(q, x) = \{(r_1, y_1, d_1), \dots, (r_k, y_k, d_k)\}$$

At each step, the NTM can non-deterministically choose which transition to make.

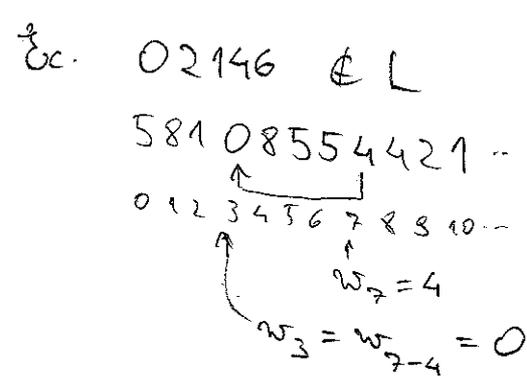

As for other ND devices: a string w is accepted if the NTM has at least one execution leading to a final state.

Example: $\Sigma = \{0, 1, \dots, 9\}$

$$L = \{w \in \Sigma^* \mid \text{a } 0 \text{ appears } i \text{ positions to the left of some } i, \text{ in } w, \text{ with } 0 < i \leq 9\} =$$

$$= \{w \in \Sigma^* \mid \exists j > 0 \text{ s.t. } w_{j-1} = 0\}$$

(w_i indicates the i -th character of w)

NTM M : s.t. $L(M) = L$

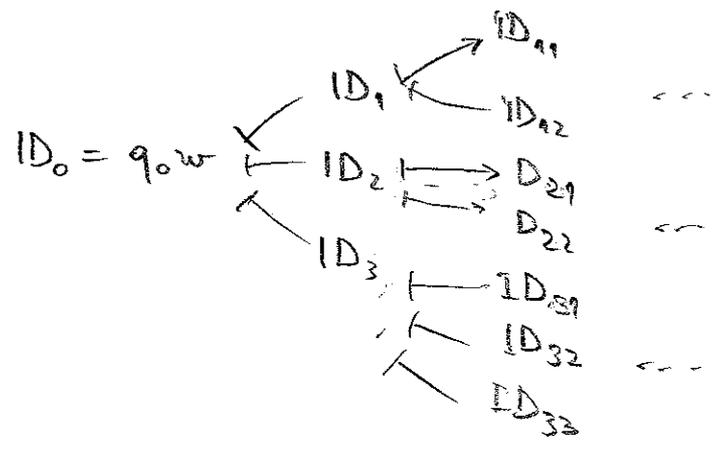

$$Q = \{q_0, f, [q, 0], [q, 1], \dots, [q, 9]\}$$

$$F = \{f\}$$

$$\Gamma = \{0, 1, \dots, 9, \emptyset\}$$

Idea for the simulation:

Consider the execution tree of N on w

DTM D will perform a breadth-first search of the execution tree, systematically enumerating the ID's, until it finds an accepting one.

We use two tapes:

tape 2: is for working

tape 1: contains a sequence of ID's of N in BFS order

- * used to separate two ID's
- $\hat{*}$ marks next ID to be explored
 - ID's to the left of $\hat{*}$ have been explored
 - ID's to the right of $\hat{*}$ are still to be explored
- initially, only $ID_0 = q_0.w$ is on the tape
- we can use multiple tracks for convenience

Algorithm: repeat the following steps

Step 0: examine current ID_c (the one after $\hat{*}$) and read q, e from it

if $q \in F$, then accept and halt

step 1: let $\delta(q, e)$ have k possible transitions

- copy ID_c onto tape 2

- make k new copies of ID_c and place them at the end of tape 1

step 2: modify the k copies of ID_c on tape 1 to become the k possible outcomes of $\delta(q, e)$ on ID_c

step 3: move $\hat{*}$ right past ID_c .

clean up tape 2

return to step 0

It is possible to verify:

- the above steps can all be implemented in a DTM

- the construction is correct, i.e. $w \in L(D)$ iff $w \in L(N)$

Evolution of tape 1:

- 1) $\hat{*} ID_0 *$
- 2) $\hat{*} ID_0 * ID_0 * ID_0 * ID_0 *$
- 3) $\hat{*} ID_0 * ID_1 * ID_2 * ID_3 *$
- 4) $* ID_0 \hat{*} ID_1 * ID_2 * ID_3 *$
- 5) $* ID_0 \hat{*} ID_1 * ID_2 * ID_3 * ID_{11} * ID_{12} *$
- 6) $* \quad \quad \quad - \quad - \quad \quad * ID_{11} * ID_{12} *$
- 7) $* ID_0 * ID_1 \hat{*} ID_2 * ID_3 * ID_{11} * ID_{12} *$
- ...

Simulation time:

8.25

- Let NTM N have running time $T(n)$.

What is the running time of D ?

Let m be the maximum number of non-det. choices for each transition (i.e., the maximum size of $\delta(q, x)$)

Consider execution tree of N on w .

let $t = T(|w|) \Rightarrow$ exec. tree has at most t levels

$$\begin{aligned} \text{size of the tree is } &\leq 1 + m + m^2 + \dots + m^t = \frac{m^{t+1} - 1}{m - 1} \\ &\equiv \frac{m^{t+1} - 1}{m - 1} = O(m^t) \end{aligned}$$

Thus D has at most $O(m^t)$ iterations of steps 0-3.

Each iteration requires at most $O(m^t)$ steps

\Rightarrow Total running time is $m^{O(t)}$, i.e. exponential
